ABSTRACT. The correct selection of the level of mechanical ballasting for wheeled tractors is among the most important issues for increasing their utilisation efficiency, in particular, increasing their grip properties. The shortcoming of the earlier undertaken investigations was that they virtually did not take into account the allowed maximum pressure of the tractor’s wheels on the soil. At the same time, little attention was paid to the impact of the maximum load-carrying capacity of the wheel tyres. The aim of the paper is to eliminate these deficiencies. Because of the authors’ efforts, the new technique has been developed, which differs in that it employs the requirement of the tyre’s ecofilic properties. The implementation of this requirement implies setting the maximum allowed level of the tractor wheels’ pressure on the soil and taking into account the maximum load-carrying capacity of the wheel tyres as well as the vertically applied load on each of the tractor’s axes under the simultaneous action of both the horizontal and vertical components of the tractive resistance of the employed agricultural implement. The practical effectiveness of the new approach is shown by the example of determining the possibility and level of ballasting the specific wheeled tractor operating as part of a ploughing unit.

Introduction

Recently, the scientists and practical experts have been more and more opting for tractor ballasting as a way of solving the problem of the efficient operation of agricultural machinery. This approach is based on the assumption that increasing the tractor’s operating weight facilitates the improvement of its grip properties. At the same time, the reduction of the specific fuel consumption takes place (Spagnolo et al., 2012; Lovarelli et al., 2018).

However, if until recently the recommended level of tractor ballasting had stayed within the range of 0–23% of the tractor’s operating weight, now many companies go for levels of 100% and even more (Boykov, Belkovskiy, 1988; Bulgakov et al., 2016). That means that, in principle, some tractors can be ballasted with weights that are equal or exceeding their operating weights.

However, it has to be remembered that the greater the vertical load per tractor wheel tyre is, the higher the soil compaction rate is (Ansorge and Godwin, 2007). Moreover, this effect is quite pronounced not only in the upper soil layer but in the lower stratum as well (Taghavifar and Mardani, 2014). That note is of great importance since the soil compaction rate is much easier to control in the upper soil layer, than in the lower one.

The operators of agricultural machinery have to keep in mind that the ballasting weight must be correctly distributed between the tractor’s axes. Otherwise, the traction efficiency of the tractor will inevitably become reduced, together with the agronomic background becoming substantially compacted (Pranav and Pandey, 2008; Nadykto et al., 2015).

In general, the draught resistance of the employed agricultural implements shapes the distribution of the vertical load between the tractor’s axes. In order to
reduce or even exclude its impact on the tractor operating in the transportation mode, the scientists have drawn the respective theoretical functional relations (Janulevičius and Giedra, 2005). However, since the paper scrutinises only the transport unit, the draught resistance of the towed implement is represented only by the horizontal component.

Moreover, the same research group have derived the equations that facilitate calculating the masses of the ballast loads needed to provide for the controlled movement of the tractor with the attached implements (Janulevičius and Giedra, 2008). Again, the vertical component of their resistance is not taken into consideration. Meanwhile, the practical experience of operating agricultural units has proved that its input in the distribution of the vertical loads between the tractor’s axles is more significant than that of the horizontal component (Bulgakov et al., 2016).

However, the most important omission in the earlier undertaken studies is that they do not include into the scope of consideration of the tractor-ballasting problem the maximum permissible pressure of its wheels on the soil (Wong and Huang, 2006; Smerda and Čupera, 2010). In addition, the maximum load-bearing capacity of the wheel tyres is paid insufficiently much attention. Whereas omitting these parameters from consideration can result in the tractor ballasting becoming either insignificant or even completely impossible, even in case double (or triple) tyres are used. Moreover, this fact is crucial, since the issue of preserving the structure, which means the fertility of the soil, is day after day becoming more urgent.

It is also worth noticing that the technique of theoretically determining the vertical loads on the tractor axles in the presence of the horizontal and vertical components of the tractive resistance of the operated agricultural implements (especially the tractor-mounted ones!) has been highlighted inadequately little in the scientific publications.

In this context, the aim of the paper is to develop such a technique for determining the tractor ballast conditions, which will take into account: a) level of the maximum permissible pressure of the tractor’s wheels on the soil; b) maximum load-bearing capacity of the wheel tyres; c) vertical load on each of the tractor’s axles, when the tractor is under the action of both the horizontal and vertical components of the draught resistance of the operated agricultural implement.

**Theoretical premises**

It is common knowledge that the ballasting of a wheeled tractor is most effective on hard surfaces, while it happens exactly on soft backgrounds that need in ballasting arises (Guskov et al., 1988; Nadykto et al., 2015). In addition, the latter ones are more prone to such a negative process as soil compaction, especially in the early spring season.

Hence, the first requirement is defined as follows: the pressure on the soil generated by the tractor’s wheels may not exceed the maximum permissible value \([Q_r]\).

The second requirement is as follows: the operating vertical load on the wheel \(N_a\) may not exceed the maximum load-bearing capacity of the tyre \(P_w\). Merging the two above-stated requirements, the following condition of the wheel tyre’s ecofilic property recommended by the authors is arrived at:

\[
\frac{N_a \leq P_w}{Q_s} \leq [Q_r],
\]

where \(F_s\) – area of the tyre’s supporting (ground contact) surface.

The parameter \(F_s\) can be calculated with a practically sufficient accuracy using the following relation:

\[
F_s = \pi \cdot H_s \cdot \sqrt{(D - H_s) - (B - H_s)},
\]

where \(H_s\) – depth of the tread generated by the wheel; \(D, B\) – diameter of the wheel and width if its tyre, respectively. In its turn:

\[
H_s = \frac{N_a < P_w}{\pi \cdot \rho_w} \cdot \sqrt{D \cdot B},
\]

where \(\rho_w\) – pressure of the air in the wheel tyre.

From the expression (1), the following condition of the possibility to ballast the tractor’s wheel results univalent:

\[
\frac{N_a \leq P_w}{Q_s} < [Q_r].
\]

Therewith, when the condition (4) is fulfilled in practice, the ballast weight per tractor wheel can be determined with the use of the following formula:

\[
M_p = (P_w - N_a) / g,
\]

where \(g\) – free-fall acceleration.

In its general form, the process of determining the possibility to ballast some specific wheeled tractor (in terms of one wheel) has the following simple algorithm (Fig. 1).

![Flow chart of algorithm for determining possibility of tractor ballasting](image)

**Figure 1. Flow chart of algorithm for determining possibility of tractor ballasting**
In the formulae (4) and (5), the parameter $N_{zk}$ – operating vertical load per wheel of the tractor, is an unknown quantity. In order to develop the method of its theoretical determination, an equivalent schematic model of the forces acting on the tractor with the mounted implement in the longitudinal and vertical plane will be analysed.

The first step is to examine the force system acting only on the tractor. For that purpose, the respective mechanical constraints will be replaced by their reactions. On the part of the mounted implement, the forces acting on the tractor are $R_{zn}$ and $R_{vn}$ (Fig. 2).

For the combination of the tractor and the mounted implement (Fig. 2 and Fig. 3), the following five forces are unknown quantities: $N_a$, $N_h$, $N_k$, $R_{zn}$, $R_{vn}$. In order to determine them, it is sufficient to have five independent equations of the tractor and implement equilibrium in the longitudinal and vertical plane.

The above-mentioned equations appear as follows:

\[
\begin{align*}
N_a - G_a + N_h - R_{zn} \cdot \sin \alpha_z - R_{vn} \cdot \sin \beta_z &= 0; \\
G_c \cdot N_v \cdot L + f \cdot R_c (N_a + N_h) + R_{zn} \cdot k_1 + R_{vn} \cdot k_2 &= 0; \\
N_h - G_h - 0.2 \cdot R_v \cdot \cos \alpha_z + R_{zn} \cdot \cos \beta_z &= 0; \\
N_k - G_h - 0.2 \cdot R_v \cdot \cos \alpha_z - R_{vn} \cdot \cos \beta_z &= 0; \\
R_x \cdot (0.2 (L_c + L_o) - h_o - h) + N_k \cdot (f \cdot r_v - L_k - L_o - f \cdot h_o) + G_p \cdot (L_p + L_o) &= 0,
\end{align*}
\]

where

\[
\begin{align*}
K_1 &= - \cos \alpha_z \cdot H_{zn} + \sin \alpha_z \cdot (G_z + L); \\
K_2 &= \cos \beta_z \cdot H_{zn} + \sin \beta_z \cdot (G_z + L); \\
L_0 &= \frac{H_{zn} + l_{zn} \cdot \tan \alpha_z \cdot \cos \beta_z + \sin \beta_z}{\tan \alpha_z + \tan \beta_z}; \\
h_o &= L_o \cdot \tan \beta_z + H_{zn} - l_{zn} \cdot \sin \beta_z
\end{align*}
\]

In the system of equations (6), $f$ – coefficient of rolling resistance; $\alpha_z$, $\beta_z$ – angles of inclination with respect to the horizontal plane of the central and lower links of the tractor’s linkage, respectively; $l_{zn}$ – length of the lower links of the tractor’s linkage; $\alpha_o$, $L_o$, $L_c$, $C_o$, $H_{zn}$, $H_{zn}$ – parameters, the meaning of which is obvious from Fig. 2 and Fig. 3.

The system of equations (6) makes it rather easy to determine the vertical reactions on the tractor axles $N_h$ and $N_k$. If the parameters of the tractor’s tyres/wheels are known and the $[Q_i]$ has been selected, then, using the equations (4) and (5), both the possibility and level of ballasting for each of the tractor axles can be determined.

It is to be noted that the system of equations (6) can easily be transformed for the case of the tractor operated with a trailing implement. For that purpose, it will be sufficient to analyse the equilibrium state of the tractor, when the implement acts on the tractor only with the force $R_{zn}$, inclined at a respective angle of $\beta_z$ to the horizontal (Fig. 2).

### Materials and Methods

The accuracy of the above-stated theoretical background was verified with the use of the ploughing unit comprising a HTZ-17221 tractor and a PLN-5-35 five-bottom force-measuring plough (Fig. 4).
Summary specification of HTZ-17221
- Operating weight force \((G_t, kN)\): 85.4
- Engine output rating (kW): 129
- Tyres: 23.1R26
- Static load per tyre (kN):
  - front axle \((N_{fa})\): 26.7
  - rear axle \((N_{ra})\): 16.0
- Static diameter of tyre \((D, m)\): 1.6
- Width of tyre section \((B, m)\): 0.587
- Maximum load-carrying capacity of tyre \((P_v, kN)\): 30.9
- Air pressure in tractor’s tyres \((p_v, kPa)\): 120

The ploughing was carried out in the autumn season. In accordance with the requirements of DSTU 4521: 2006 “Mobile agricultural machinery”, the maximum permissible pressure of the tractor wheels on the soil \(\bar{D} \) was assumed at 160 kPa.

The tractor weight force \((G_t)\) and its distribution between the axles \((N_{fa}, N_{ra})\) as well as the plough weight force \((G_p)\) were determined by weighing them with the use of the DPU-5 load gauge to an accuracy of 0.5 kN. The obtained resulting data were used for determining the longitudinal coordinate of the tractor’s centre of mass \(a_t\) with the use of the following formula:

\[
a_t = \frac{N_{fa}L_t}{a_t}, \tag{7}
\]

where \(L_t\) – tractor’s wheelbase (Fig. 2). This parameter, as well as the linear parameters \(L_c, L_k, L_p, r_k, C_z, H_{zn}, H_{zn}v\) and \(l_z\), were measured with the use of a gauge tape to an accuracy of 1 cm.

During the field-testing of the ploughing unit, the tractor travelled on the stubble field of winter wheat. In order to determine the coefficient of rolling resistance \(f\), the tested tractor together with the plough were towed by another tractor. The effort applied for the translation of the ploughing unit \((P_f)\) in the five test repetitions was registered with the use of the strain-gauge link that sent a signal to the analogue-digital converter, which transmitted it to the PC. The required unknown coefficient was determined with the use of the following expression:

\[
f = \frac{p_f}{G_t+G_p}, \tag{8}
\]

The draught resistance of the plough \((R_s)\) was measured with the use of the draught strain-gauge link installed on it (Fig. 5).

The signal from that link was registered in the PC after being processed by the analogue-digital converter. The ploughing unit was set up for three different tilling depths: 22, 25 and 28 cm. The travelling velocity of the unit during its ploughing to each of the specified depths was determined on a leg with a length of 250 m in two repetitions (travelling ahead and returning). The unit travelling time \(\bar{t}\) was measured to an accuracy of 0.2 s with the use of the COC-26-2-000 stopwatch. On the same leg, the effective rolling radius of the tractor wheel \(R_k\) was determined. This was done with the use of the following formula:

\[
R_k = \frac{60 \cdot 250}{\pi \cdot \bar{t} \cdot n_w^i}, \tag{9}
\]

where \(n_w^i\) – number of the tractor wheel’s revolutions. This parameter was registered with the use of hermetically sealed reed relay sensors (Fig. 6).

After each run of the unit, the depth of tilling was measured with the use of a mechanical depth gauge. The measurement spacing was 1 m, the number of measurements – at least 200.

The following statistical characteristics were computed for the arrays of data on the plough draught resistance and the depth of ploughing: mean, variance, coefficient of variation, correlation function and spectral density.

The data obtained as a result of the measurements were input into the system of equations (6) in order to determine the vertical reactions on the front \((N_{fa})\) and rear \((N_{ra})\) axles of the tractor. Then, using the formulae (4) and (5), the possibility and level of the tractor axle ballasting were found.

![Figure 5. Draught strain-gauge link](image)

![Figure 6. Wheel rpm pickup](image)
Results and Discussion

First, the assessment is to be done of the impact of the plough’s oscillations on the tractor. This assessment will take into account the fact that the more stable its traction load is, the more stable values of the vertical loads on the tractor axles are.

In their turn, the stability of the plough draught resistance oscillations (force $R_x$, Fig. 3) is largely defined by the characteristics of the tilling depth (parameter $h$) oscillations.

The analysis of the experimental data has shown that the variance of this parameter’s oscillations does not substantially differ for different tilling depths (Table 1). According to the F-test of Fischer, it can be stated with a confidence level of 95% that the null hypothesis of the equality of the compared variances is not rejected.

The coefficient of variation of the ploughing depth oscillations at all depth values does not exceed 6%. That indicates that the process under consideration has low variability (Dospehov, 1985). Moreover, it turns out to be also a low-frequency process. This conclusion results from the analysis of the normalized correlation functions of the ploughing depth oscillations (Fig. 7).

As can be seen in the diagrams presented in Fig. 7, the length of correlation for all three functions is equal to about 3.5 m. That means that this is the distance, at which the correlation between the tilling depth values disappears virtually completely. Admittedly, the said length of correlation suggests the low frequency of the process of oscillation of the depth, to which the unit under investigation ploughs the soil. Moreover, it is virtually stochastic, since the analysed normalized correlation functions do not contain any more or less pronounced periodic components.

The low variability of the ploughing depth oscillations (i.e. the parameter $h$) is reflected respectively in the characteristics of the plough draught resistance (force $R_x$) oscillations. As is proved by the analysis of the experimental data (Table 1), the variance of these parameter oscillations is virtually independent on the tilling depth. Again, in accordance with the F-test of Fischer, the difference between its values is statistically random. Also, since the values of the coefficient of variation stay within 10% (Table 1), the process under consideration is a low variability one (Dospehov, 1985).

The frequency spectrum of the plough draught resistance oscillations can be assessed by analysing the respective normalized spectral densities (Fig. 8).

The analysis has shown that the cut-off frequency for the normalized spectral densities of the $R_x$ force oscillations is within the range of 16–18 s^{-1} (i.e. 2.5–2.9 Hz) for all the three ploughing depth settings. The maximums of the plough draught resistance oscillation variances are observed within the frequency range of 0 to 6 s^{-1}, which altogether does not exceed 1 Hz. All that unequivocally indicates that the oscillations with such characteristics are low-frequency oscillations.

It is appropriate to suggest that the stable properties of the variation of the tilling depth and the plough draught resistance oscillations provide no ground for any significant oscillations of the vertical load on the tractor’s axles. For the purposes of the theoretical computation, they can be assumed, to a first approximation, to be virtually constant.

Using the measurement results obtained during the experiments and the system of equations (6), the vertical loads on the front ($N_a$) and rear ($N_b$) axles of the tractor have been obtained (see Table 1). The calculations have been done with the use of the following values for the parameters in the system of equations (6):

$$G_t = 85.4 \text{ kN}; \quad G_\rho = 8.4 \text{ kN}; \quad L = 2.86 \text{ m}; \quad f = 0.07; \quad \alpha_1 = 1.1; \quad \alpha_2 = 0.2; \quad L_1 = 1.7 \text{ m}; \quad L_2 = 1.5 \text{ m}; \quad L_3 = 1.5 \text{ m}; \quad C_1 = 0.4 \text{ m}; \quad l_\rho = 0.93 \text{ m}; \quad \alpha_3 = 5\degree; \quad \beta_1 = 1\degree; \quad R_0 = 0.78-0.80 \text{ m}; H_\rho = 1.2 \text{ m}; H_\eta = 0.45 \text{ m}.$$

The values of the variable parameters $h$ and $R_x$ are shown in Table 1. The analysis has determined that, in the presence of a draught load, considerable redistribution of the vertical loads on the tractor axles takes place. Specifically, the vertical load on the front axle decreases and on the rear axle increases. Overall, additional loading of the whole tractor takes place. The characteristic of this process is shown in Fig. 9.

As is obvious, the greater the plough draught resistance is, the greater the additional vertical load on the tractor becomes, even though at an insignificant rate (by 2-3 kN). Together with the operating weight ($G_t = 85.4 \text{ kN}$), this makes up the adhesion weight of the tractor within the range of 87.4-88.4 kN. The further calculations with the use of the formulae (4) and (5) have been carried out using the following values of their parameters: $N_d = N_a \text{ or } N_b; \quad [Q_t] = 160 \text{ kPa}; \quad D = 1.6 \text{ m}; \quad P_\pi = 30.9 \text{ kN}; \quad \beta_\rho = 120 \text{ kPa}; \quad B = 0.587 \text{ m}.$

The results of calculations show that the front axle of the tractor under consideration when operated with a plough, can be in principle additionally loaded with a weight at a rate of 1140 kg. However, in reality this is not to be done. The reason is as follows. When the tractor travels without a traction load (or stands), the vertical reaction on its front axle is \( M_0 = 53.4 \text{ kN} \). If the ballast weight equal to \((1140 \cdot 9.81)/1000 = 11.2 \text{ kN} \) is added to it, the resulting sum will be \( M_0 + 11.2 = 64.6 \text{ kN} \). However, that violates the condition (4). In accordance with the expression (5), the maximum ballast weight that can be used to load additionally the front axle of the tractor under consideration may not exceed 900 kg. However, if the maximum permissible pressure of the wheels on the soil is set at \( [Q_p] = 130 \text{ kPa} \), then this ballasting weight (i.e. 900 kg) will also become unacceptable.

The front axle of a HTZ-17221 tractor, when operated with a plough, can be additionally loaded, as follows from formula (4), by a weight of 2500 kg. In that case, if the maximum permissible pressure of the wheels on the soil is set at \( [Q_p] = 130 \text{ kPa} \), the maximum permissible ballasting of the tractor will be not greater than 530 kg.

Overall, if \( [Q_p] = 160 \text{ kPa} \), the total ballasting weight on a HTZ-17221 tractor planned to be used with a five-bottom plough with a working width of 1.75 m may not exceed \( M_0 = 900 + 2,500 = 3,400 \text{ kg} \). However, this value is equal to only 39% of the operating weight of the above-mentioned tractor.

At \( [Q_p] = 130 \text{ kPa} \), ballasting this tractor is altogether not allowed. Otherwise, that will result in both overloading the tractor’s tyres and inexcusably strong compaction of the soil, the fertility of which has to be maintained at all times. Ballasting such a tractor at \( [Q_p] = 130 \text{ kPa} \) becomes possible only in case of using twin tyres. However, that engineering solution is technologically impracticable in case of operating the HTZ-17221 tractor with a plough.

### Conclusions

Improving the efficiency of operation of wheeled tractors by means of increasing their grip properties can be achieved through the correct selection of the level of their mechanical ballasting. When solving the problem of ballasting wheeled tractors, it is suggested to take as the basis the new condition of the ecofilic property of the tyre. The devised technique of the practical implementation of this condition implies: 1) deciding on (setting) the maximum permissible pressure of the tractor wheels on the soil; 2) taking into account the maximum load-carrying capacity of the wheel tyres of the specific tractor; 3) finding out / taking into account the real values of the vertical loads on each of the tractor axles, when both the horizontal and vertical components of the draught resistance of the operated agricultural implement act on the tractor.

The specific example of application of the devised technique has revealed that, when a tractor with an operating weight of about 8700 kg and the maximum permissible pressure of the wheels on the soil of 160 kPa unitised with a plough with a working width of 1.75 m is used, the maximum permissible level of ballast on the engine unit may not exceed 39% of its weight. If the permissible pressure of the wheels on the soil is set at \( [Q_p] = 130 \text{ kPa} \), ballasting the tractor under consideration is altogether not allowed.
